### THE STACK AND THE STACK POINTER

- Sometimes it is useful to have a region of memory for temporary storage, which does not have to be allocated as named variables.

- When we use subroutines and interrupts it will be essential to have such a storage region.

- Such a region is called a *Stack*.

- The *Stack Pointer* (SP) register is used to indicate the location of the last item put onto the stack.

- When you put something onto the stack (push onto the stack), the SP is decremented *before* the item is placed on the stack.

- When you take something off of the stack (pull from the stack), the SP is incremented *after* the item is pulled from the stack.

- Before you can use a stack you have to initialize the Stack Pointer to point to one value higher than the highest memory location in the stack.

- For the MC9S12 put the stack at the top of the data space

    - For most programs, use $1000 through $2000 for data.
    - For this region of memory, initialize the stack pointer to $2000.
    - If you need more space for data and the stack, and less for your program, move the program to a higher address, and use this for the initial value of the stack pointer.

  .

- Use the LDS   (Load Stack Pointer) instruction to initialize the stack point.

- The LDS instruction is usually the first instruction of a program which uses the stack.

- The stack pointer is initialized only one time in the program.

- For microcontrollers such as the MC9S12, it is up to the programmer to know how much stack his/her program will need, and to make sure enough space is allocated for the stack. If not enough space is allocated the stack can overwrite data and/or code, which will cause the program to malfunction or crash.

The stack is an array of memory dedicated to temporary storage

**SP points to location last item
placed in block**

**SP decreases when you put item on stack**

**SP increases when you pull item from stack**

**For MC9S12, use 0x2000 as initial SP:**

```
STACK:    EQU    $2000
          LDS    #STACK
```

**STACK:  equ   $2000**

**CODE:    org $2000**

```
lds      #STACK
ldaa     #$2e
ldx      #$1254
psha
pshx
clra
ldx       #$ffff
```

**CODE THAT USES A & X**

```
pulx
pula
```

**A**

**X**

**SP**

# PSHA      Push A onto Stack      PSHA

**Operation**  $(SP) - \$0001 \Rightarrow SP$
$(A) \Rightarrow M_{SP}$

Decrements SP by one and loads the value in A into the address to which SP points.

Push instructions are commonly used to save the contents of one or more CPU registers at the start of a subroutine. Complementary pull instructions can be used to restore the saved CPU registers just before returning from the subroutine.

### Subroutines

- A subroutine is a section of code which performs a specific task, usually a task which needs to be executed by different parts of a program.

- Example:

  – Math functions, such as *square root*

- Because a subroutine can be called from different places in a program, you cannot get out of a subroutine with an instruction such as

  ```
  jmp     label
  ```

  because you would need to jump to different places depending upon which section of code called the subroutine.

- When you want to call the subroutine your code has to save the address where the subroutine should return to. It does this by saving the *return address* on the stack.

  – This is done automatically for you when you get to the subroutine by using the JSR (Jump to Subroutine) or BSR (Branch to Subroutine) instruction. This instruction pushes the address of the instruction following the JSR (BSR) instruction on the stack.

- After the subroutine is done executing its code it needs to return to the address saved on the stack.

  – This is done automatically for you when you return from the subroutine by using the RTS (Return from Subroutine) instruction. This instruction pulls the return address off of the stack and loads it into the program counter, so the program resumes execution of the program with the instruction following that which called the subroutine.

  The subroutine will probably need to use some MC9S12 registers to do its work. However, the calling code may be using its registers for some reason — the calling code may not work correctly if the subroutine changes the values of the MC9S12 registers.

  – To avoid this problem, the subroutine should save the MC9S12 registers before it uses them, and restore the MC9S12 registers after it is done with them.

# BSR                    **Branch to Subroutine**                    BSR

**Operation**   $(SP) - \$0002 \Rightarrow SP$
$RTN_H{:}RTN_L \Rightarrow M_{SP}{:}M_{SP+1}$
$(PC) + \$0002 + rel \Rightarrow PC$

Sets up conditions to return to normal program flow, then transfers control to a subroutine. Uses the address of the instruction after the BSR as a return address.

Decrements the SP by two, to allow the two bytes of the return address to be stacked.

Stacks the return address (the SP points to the high byte of the return address).

Branches to a location determined by the branch offset.

Subroutines are normally terminated with an RTS instruction, which restores the return address from the stack.

# RTS                    **Return from Subroutine**                    RTS

**Operation**  $(M_{SP}):(M_{SP+1}) \Rightarrow PC_H:PC_L$
$(SP) + \$0002 \Rightarrow SP$

Restores the value of PC from the stack and increments SP by two. Program execution
continues at the address restored from the stack.

Example of a subroutine to delay for a certain amount of time

```
; Subroutine to wait for 100 ms

delay:  ldaa    #100    ; Execute outer loop 100 times
loop2:  ldx     #8000   ; Want inner loop to last 1 ms
loop1:  dbne    x,loop1 ; Inner loop  -- 3 cycles x 8000 times
        dbne    a,loop2
        rts
```

- Want inner loop to last for 1 ms. MC9S12 runs at 24,000,000 cycles/second, so 1 ms is 24,000 cycles.

- Inner loop should be 24,000 cycles/ (3 cycles/loop) = 8,000 times

- Problem: The subroutine changes the values of registers `A` and `X`

- To solve, save the values of `A` and `X` on the stack before using them, and restore them before returning.

```
; Subroutine to wait for 100 ms

delay:  psha            ; Save regs used by sub on stack
        pshx
        ldaa    #100    ; Execute outer loop 100 times
loop2:  ldx     #8000   ; Want inner loop to last 1 ms
loop1:  dbne    x,loop1 ; Inner loop  -- 3 cycles x 8000 times
        dbne    a,loop2
        pulx            ; Restore regs in opposite
        pula            ; order
        rts
```

```
; Program to make a binary counter on LEDs
;

### Another example of using a subroutine

Using a subroutine to wait for an event to occur, then take an action.

- Wait until bit 7 of address $00C4 is set.

- Write the value in ACCA to address $00C7.

```
; This routine waits until the MC9S12 serial
; port is ready, then sends a byte of data
; to the MC9S12 serial port

putchar:        brclr      $00CC,#$80,putchar
                staa       $00CF
                rts
```

- Program to send the word `hello, world!` to the MC9S12 serial port

```
; Program fragment to write the word "hello, world!" to the
; MC9S12 serial port

                ldx        $str
loop:           ldaa       1,x+     ; get next char
                beq        done     ; char == 0 => no more
                jsr        putchar
                bra        loop
                swi

str:            dc.b       "hello, world!"
                fc.b       $0A,$0D,0    ; CR LF
```

Here is the complete program to write a line to the screen:

```
prog:     equ      $2000
data:     equ      $1000
stack:    equ      $2000
SCI0SR1:  equ      $00CC   ; SCI0 status reg 1
SCI0DRL:  equ      $00CF   ; SCI0 data reg low

          org      prog
          lds      #stack
          ldx      #str
loop:     ldaa     1,x+ ; get next char
          beq      done ; char == 0 => no more
          jsr      putchar
          bra      loop
done:     swi

putchar:  brclr    SCI0SR1,$80,putchar
          staa     SCI0DRL
          rts

          org      data
str:      fcc      "hello, world"
          dc.b     $0a,$0d,0 ; CR LF terminating zero
```

### Using DIP switches to get data into the MC9S12

- DIP switches make or break a connection (usually to ground)

# DIP Switches on Breadboard
- To use DIP switches, connect one end of each switch to a resistor

- Connect the other end of the resistor to +5 V

- Connect the junction of the DIP switch and the resistor to an input port on the MC9S12

- The Dragon12-Plus has eight dip switches connected to Port H (`PTH`).

## Using DIP Switches

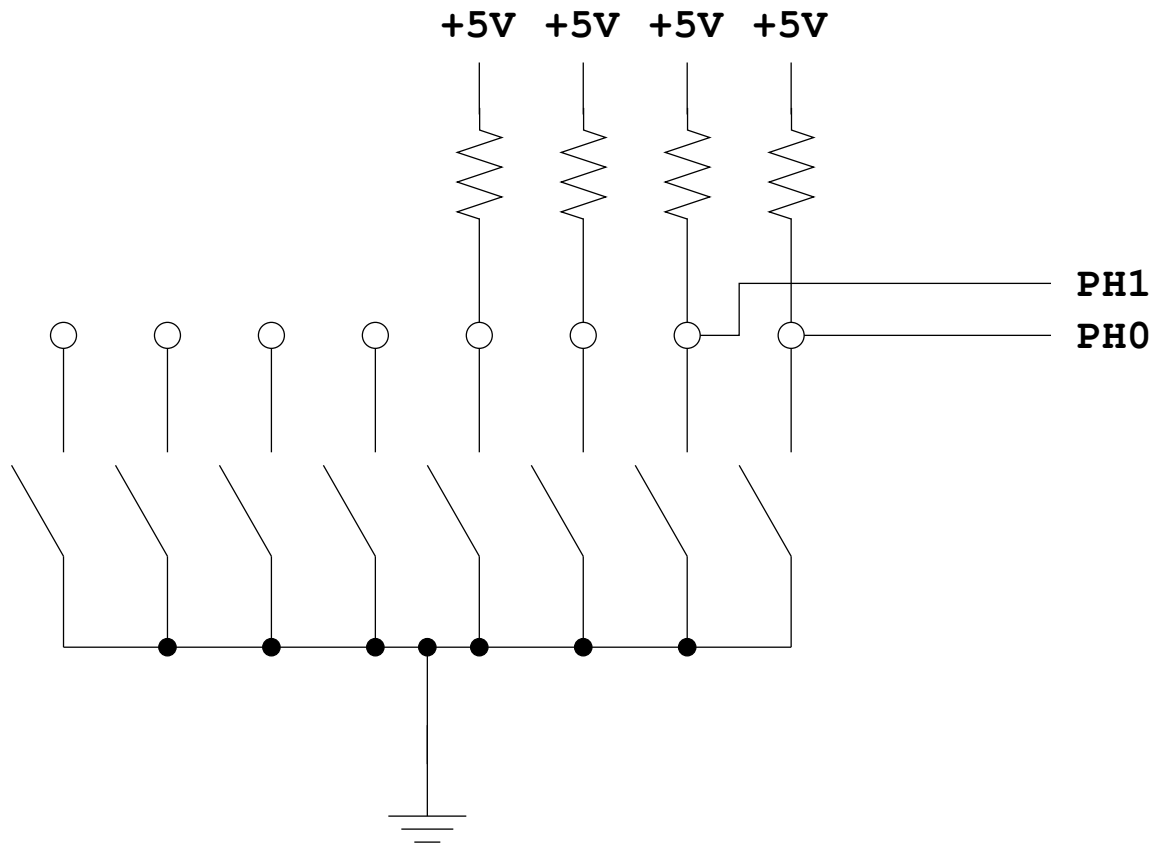

- When the switch is open, the input port sees a logic 1 (+5 V)

- When the switch is closed, the input sees a logic 0 (0 V)

## Looking at the state of a few input pins

- Want to look for a particular pattern on 4 input pins

    - For example want to do something if pattern on PB3-PB0 is 0110

- Don't know or care what are on the other 4 pins (PB7-PB4)

- Here is the wrong way to do it:

```
ldaa    PTH
cmpa    #$06
beq     task
```

- If PH7-PH4 are anything other than 0000, you will not execute the task.

- You need to mask out the Don't Care bits **before** checking for the pattern on the bits you are interested in
```
ldaa    PTH
anda    #$0F
cmpa    #$06
beq     task
```

- Now, whatever pattern appears on PB7-4 is ignored

Using an MC9S12 output port to control an LED

- Connect an output port from the MC9S12 to an LED.

# Using an output port to control an LED

**PAO**

Resistor, LED, and
ground connected
internally inside
breadboard

When a current flows
through an LED, it
emits light

### Making a pattern on a seven-segment LED

- Want to generate a particular pattern on a seven-segment LED:

- Determine a number (hex or binary) which will generate each element of the pattern

  - For example, to display a 0, turn on segments `a, b, c, d, e and f`, or bits `0, 1, 2, 3, 4` and `5` of `PTB`. The binary pattern is `00111111`, or `$3f`.

  - To display `0 2 4 6 8`, the hex numbers are `$3f, $5b, $66, $7d, $7f`.

- Put the numbers in a table

- Go through the table one by one to display the pattern

- When you get to the last element, repeat the loop
